"BRIE looks at both sides" — for the positions, yes; for the rate, no

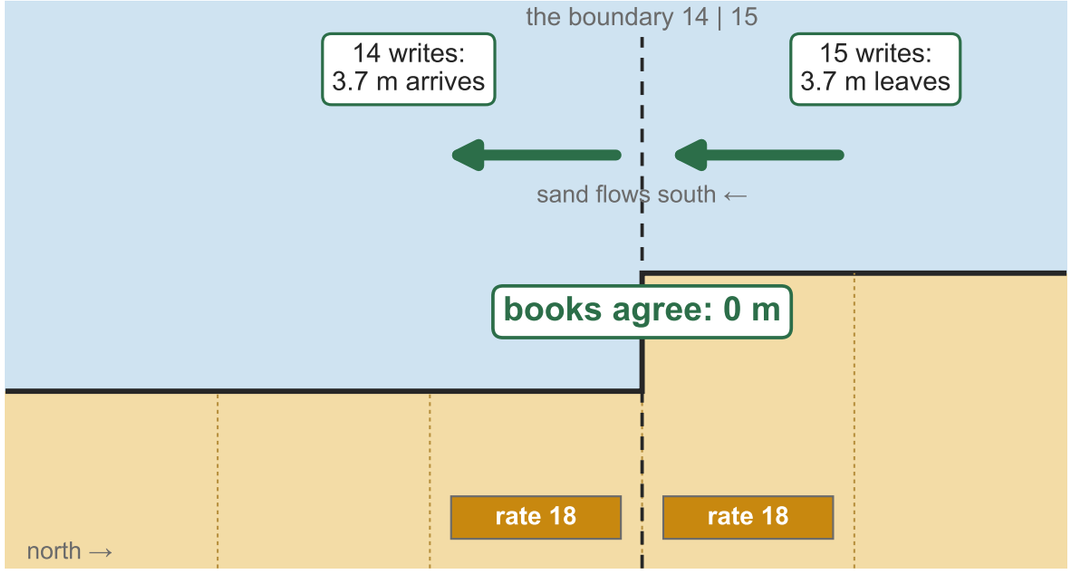
BRIE's update for one section, every year (brie.py 1311-1324):

$$x[i] \mathrel{+}= r[i] \times \left(x[i+1] - 2 \cdot x[i] + x[i-1] \right)$$

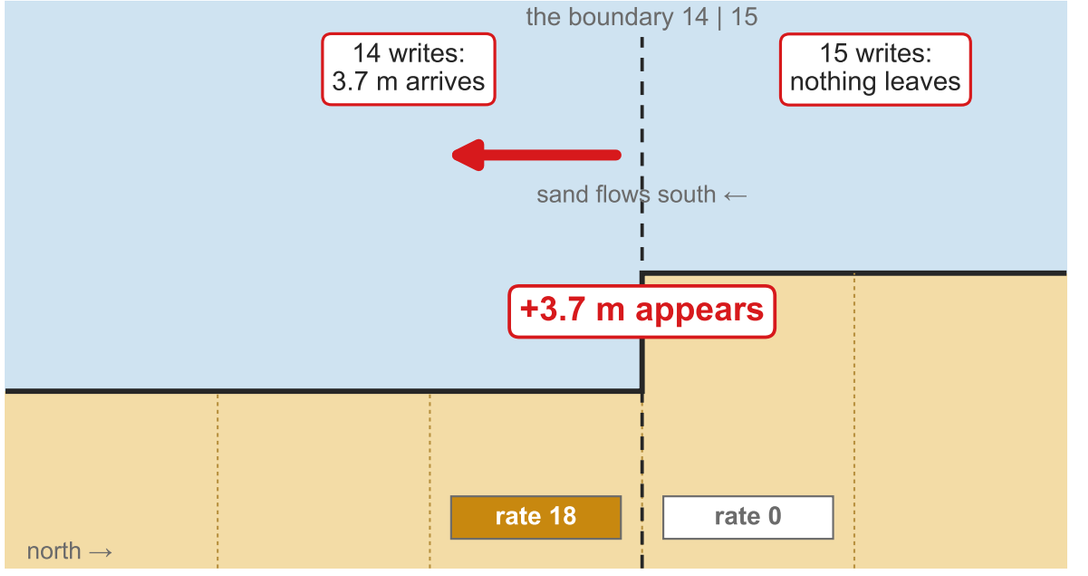
ONE rate, from the angle of the NORTH boundary only (brie.py 820-826), used on both sides

positions from BOTH sides (north and south): true this is what "it looks at both sides" means

If both sections used the same rate



What BRIE does: each uses its own north boundary's rate



Add up every section's change and the positions cancel, but each boundary leaves behind
(rate of the section to its south − rate of the section to its north) × (the step across the boundary)

Neighbours' rates match (a straight coast, or one curving smoothly): about 0. Rates jump between neighbours (a bend or a kink): sand made or lost.
